1. Water in the Atmosphere

The earth’s surface extends from the surface to about 700km. Hydrologic processes occur almost exclusively in the troposphere. This layer extends approximately 12km above the surface and the lowest km is the boundary layer, the layer that is directly affected by the surface. While vertical temp and pressure gradients vary with latitude, season and local weather patterns, averaged spatially and temporally the following temperature structure arises:

Figure 2: Layers of the atmosphere and their mean temperature. From Ahrens

As can be seen, the vertical temperature gradient in the troposphere, called a **lapse rate**, has an average value of $-6.5 \, ^\circ C km^{-1}$. In some cases, like during cold nights, the temperature gradient near the surface may temporarily reverse direction - this is called and **inversion**.

1a. Temperature-pressure relations

Temperature, pressure and density in the atmosphere are related via the Ideal Gas Law:
\[ \frac{P}{T_a \rho_a} = R_a \]  

where \( P \) is the atmospheric pressure, \( T_a \) is air temperature, \( \rho_a \) is mass density of air in \( \text{kg/m}^3 \) and \( R_a \) is the gas constant [for dry air \( R_a = R_d = 287 \text{ Jkg}^{-1} \text{K}^{-1} \)]. This law states that an increase (decrease) in pressure is always accompanied by an increase (decrease) in temperature and density. So when a parcel moves to a region of lower pressure it cools. These processes don’t have an associated input or removal of heat so they are \textbf{adiabatic} processes.

\textbf{1b. Water Vapor}

All of the molecules that compose air (including \( \text{H}_2\text{O} \)) are in constant motion with velocities on the order of 550 ms\(^{-1}\). Each of the gases in a gas mixture (such as the atmosphere) exerts a pressure called a \textbf{partial pressure}, which is proportional to its concentration. The sum of the partial pressures of the gasses equals the total atmospheric pressure. The partial pressure of water vapor is called the \textbf{vapor pressure} and is designated \( e \).

\textbf{Saturation vapor pressure} (\( e^* \)) is the partial pressure of the water vapor in equilibrium with a plane surface of pure water. It is a function of temperature alone, so \textit{it doesn’t depend on the vapor content of the air}. \( e^* \) is highly nonlinear, as it increases rapidly with temperature. This behavior is extremely important and explains why the amount of atmospheric water vapor will likely increase with global warming.

\[ e^* = .611 \exp \left( \frac{17.3T}{T + 237.3} \right) \]  

where \( e^* \) is in \( \text{kPa} \) and \( T \) is in \( ^\circ\text{C} \). This is an empirical relation, and there are many of these relations. This is the one we will use in this class.

The \textbf{absolute humidity} or \textbf{vapor density} is the mass concentration of water vapor in a volume of air. Using the ideal gas law:

\[ \frac{e}{T_a \rho_v} = R_v \]  

\textbf{Specific humidity} (\( q \)) is the concentration of water vapor expressed as the mass of water vapor per unit mass of moist air. Thus we have:
Figure 3: Explanation of Saturation vapor pressure. From Ahrens

Figure 4: Absolute humidity. From Ahrens
where 

\[ q = \frac{m_v}{m_v + m_d} = \frac{\rho_v}{\rho_d + \rho_v} \]  

\[ = \frac{e / R_a T_a}{(P - e) R_d T_a + e / R_v T_a} = 0.622 \frac{e}{P - (1 - 0.622)e} \approx 0.622 \frac{e}{P} \]  

\[ \text{(4)} \]

\[ \]  

\[ \text{Figure 5: Specific humidity. From Ahrens} \]

The **saturation specific humidity** \((q^*)\) is defined as:

\[ q^* = 0.622 \frac{e^*}{P - (1 - 0.622)e^*} \approx 0.622 \frac{e^*}{P} \]  

\[ \text{(5)} \]

**Mixing ratio** is the mass of water vapor per unit mass of dry air:

\[ r = \frac{m_v}{m_d} = \frac{\rho_v}{\rho_d} = \frac{e / R_a T_a}{(P - e) / R_d T_a} = 0.622 \frac{e}{P - e} \approx 0.622 \frac{e}{P} \]  

\[ \text{(6)} \]

The **saturation mixing ratio** \((r^*)\) is defined as:

\[ r^* = 0.622 \frac{e^*}{P - e^*} \approx 0.622 \frac{e^*}{P} \]  

\[ \text{(7)} \]

**Relative humidity** can be defined in one of three different ways:

\[ W_a = 100 \frac{e}{e^*} \text{ or } W_a = 100 \frac{q}{q^*} \text{ or } W_a = 100 \frac{r}{r^*} \]  

\[ \text{(8)} \]

it is expressed as a percent. It is the degree to which the air is saturated. Any value less than 100% means that the air is unsaturated. Cooling a parcel brings it closer to saturation. Air can have Wa values in excess of 100%, at these points the air is **supersaturated**.
Dew Point (Td) is the temperature to which a parcel with a given vapor pressure has to be cooled in order to reach saturation. From its definition:

\[ r = r \ast (T_d, P) = 0.622 \frac{e \ast (T_d)}{P - e \ast (T_d)} \]  

(9)

This is an implicit equation, which we can solve by plotting or by Newton-Raphson iterations. However, we can calculate is using an approximation as:

\[ T_d = \frac{ln(e) + 0.4926}{.0708 - .00421ln(e)} \]  

(10)

where \( T_d \) is in °C and \( e \) is in kPa.
